

Human Cognitive Emulation

by Lee Rumpf

2006-2007 Period 3 TJHSST Computer Systems Techlab

-Abstract-

This project attempts to accurately model human responses to stimuli. Using a survey format and decision tree learning, this research hopes to produce a unique response to a stimuli based on information gained about the user. Analyzed solely on its own, the ramification of this project can perhaps draw broad conclusions about groups of people and how they respond. When combined with other techniques of emulating human thought patterns, computer programs can come closer to representing accurately human responses.

-Procedure and Results-

To get data, a survey was posted on the TJ Intranet and filled out by over 250 seniors. It asked 14 questions about various aspects of their academic and social life, followed by three questions of interest. The questions of interest were 1) After attending TJ, do you plan on continuing with physical science/math as your focus? 2) How prepared do you feel for college academics? And 3) How prepared do you feel for college life? After the data was gathered it was converted to a csv file and used to make a tree. To test, the user simply follows the tree down from "trunk" to "branch". If, when the user reaches the bottom of the tree, the answer the tree gives to the qualifier is equal to the users answer, the program was a success. When all was done, the program produced mostly accurate answers/predictions, but because of the detail of the tree the best results actually arise from the math within ID3. The level of the tree determines importance, and so Time in the Systems Lab, Whether or not a student takes higher math, and Time in Sports were the most important factors in question 1, 2, and 3 respectively.

-Methods and Procedures-

ID3 is the heart of Decision Tree Learning. It was developed in 1975 and I use it in LISP

```
(defun id3 (examples target.attribute attributes)
  (let (firstvalue a partitions)
    (setq firstvalue (get.value target.attribute (first examples)))
    (cond
      ((every #'(lambda(e)(eq firstvalue (get.value target.attribute e))) examples)
       firstvalue)
      ((null attributes)
       (most.common.value target.attribute examples))
      (t
       (setq partitions
             (loop for a in attributes collect (partition a examples)))
       (setq a (choose.best.partition target.attribute partitions))
       (cons (first a)
             (loop for branch in (cdr a) collect
                   (list (first branch)
                         (id3 (cdr branch)
                               target.attribute
                               (remove (first a) attributes))))))))))
```

The screenshot shows a web browser window with a survey titled "TJHSST Intranet2: Polls...". The survey consists of 17 questions. Question 10 asks about race with options: Clear Vote, White, Asian, Wasian, and Other. Question 11 asks if the user took AP Chem with options: Clear Vote, Yes, and No. Question 12 asks if the user took AP Physics with options: Clear Vote, Yes, and No. Question 13 asks if the user took AP Bio with options: Clear Vote, Yes, and No. Question 14 asks if the user took Multivar/Linear Algebra with options: Clear Vote, Yes, and No. Question 15 asks if the user plans to continue with physical science/math after attending TJ with options: Clear Vote, Yes, and No. Question 16 asks how prepared the user feels for college academics with options: Clear Vote, Well Prepared, Prepared, and Not Prepared. Question 17 asks how prepared the user feels for college life with options: Clear Vote, Well Prepared, Prepared, and Not Prepared.

Entropy is used to calculate the information gain of each classifier. To the right is a graph of entropy vs. p. Where p is the proportion of examples positive and negative
